# 1 Introduction

The objective of the assignment is to develop a machine learning model to predict the dependent variables (insurance charges and house price) based on the independent variables following datasets.

- I. Insurance data set
- II. Real estate dataset

## 1.1 Road map

To achieve the target following procedural steps were adopted:

- Data cleaning
- Data visualization
- Dividing the data into label(dependent variable) and features (independent variables)
- Splitting the data into training and test sets
- Finding an appropriate model with suitable hyperparameters with the help of GridSearchCV
- Training the model with training data
- Validating the model on train and test sets with different scoring parameters

## 2 Data Cleaning

Firstly, the data were checked for missing or null values. To quantify the null values “isnull().any()” command was used. The command reported no null values in both the data sets.

# Null values in Insurance Data Set df.isnull().any()		# null values in real estate dataset df.isnull().any()	
age	False	Transaction date	False
sex	False	House age	False
bmi	False	Distance to the nearest MRT station	False
children	False	Number of convenience stores	False
smoker	False	Latitude	False
region	False	Longitude	False
charges	False	House price of unit area	False
dtype: bool		dtype: bool	

Figure 1: Null value reports for insurance and real estate data respectively

Python’s ‘info()’ command provided the information that all the attributes, other than categorical data, contained numerical values.

```
# Information about attributes | data types
print(df.info())

<class 'pandas.core.frame.DataFrame'>
RangeIndex: 1338 entries, 0 to 1337
Data columns (total 7 columns):
#   Column      Non-Null Count  Dtype
---  -
0    age         1338 non-null   int64
1    sex         1338 non-null   object
2    bmi         1338 non-null   float64
3    children    1338 non-null   int64
4    smoker      1338 non-null   object
5    region      1338 non-null   object
6    charges     1338 non-null   float64
dtypes: float64(2), int64(2), object(3)
```

Figure 2: Information about the attributes of real estate data

One hot encoding technique was implemented to tackle with categorical data which will be discussed latter.

Python’s ‘missingno’ library was used to visualize the missing data if any. Following charts show that all the features of the data set contain same number of values and no missing data is reported.

**Figure 3: Missing value chart for insurance dataset**

**Figure 4: Missing value chart for real estate dataset**

### 3 Data Visualization

#### 3.1 Pair plot

Pair plots were used to quickly visualize patterns and relationships between different features of dataset.

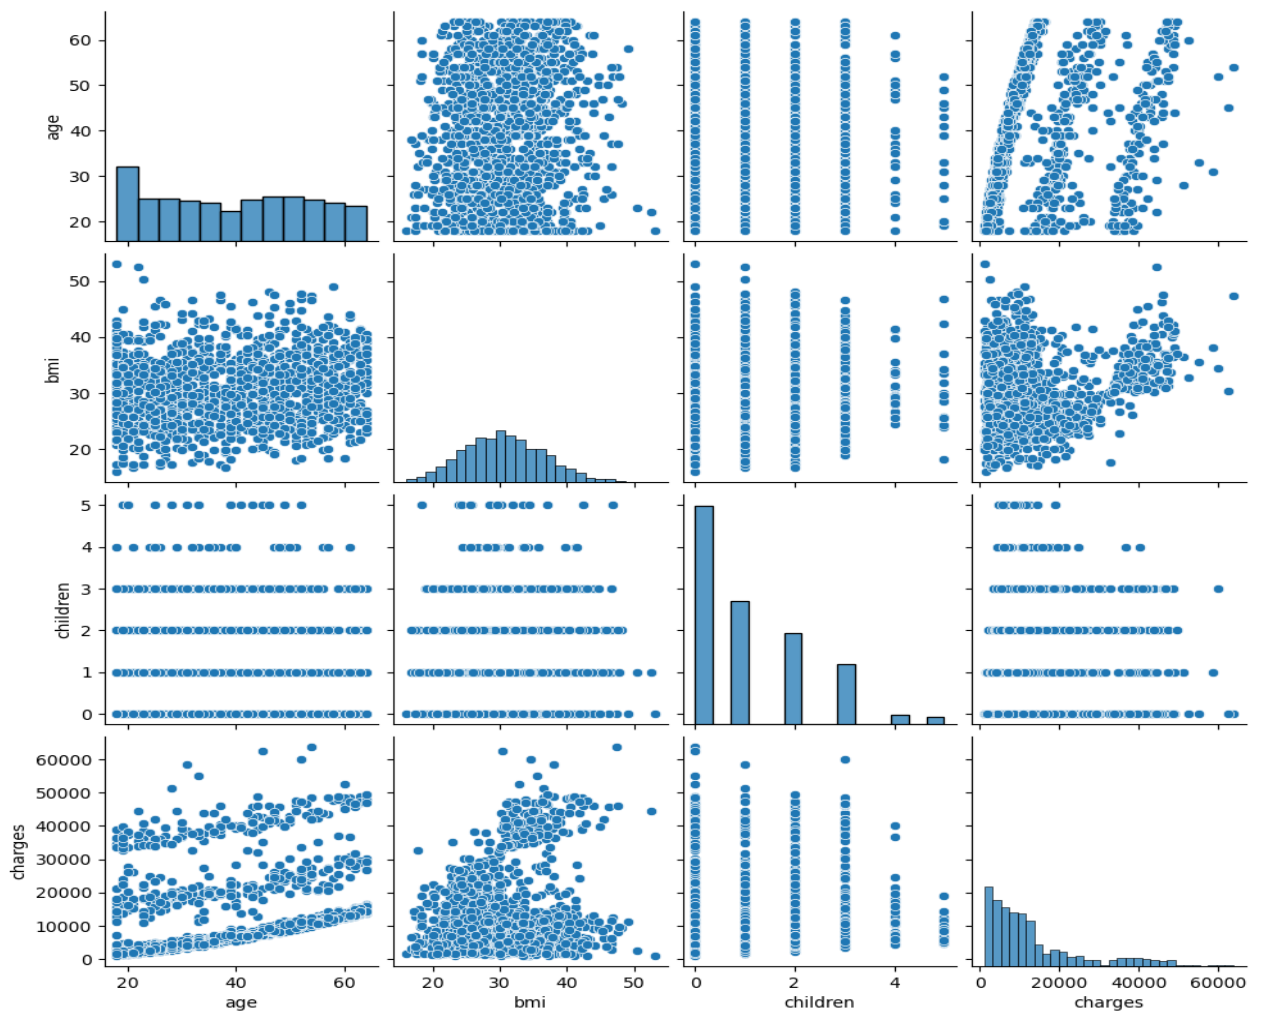

Figure 5: Pair plots for insurance dataset

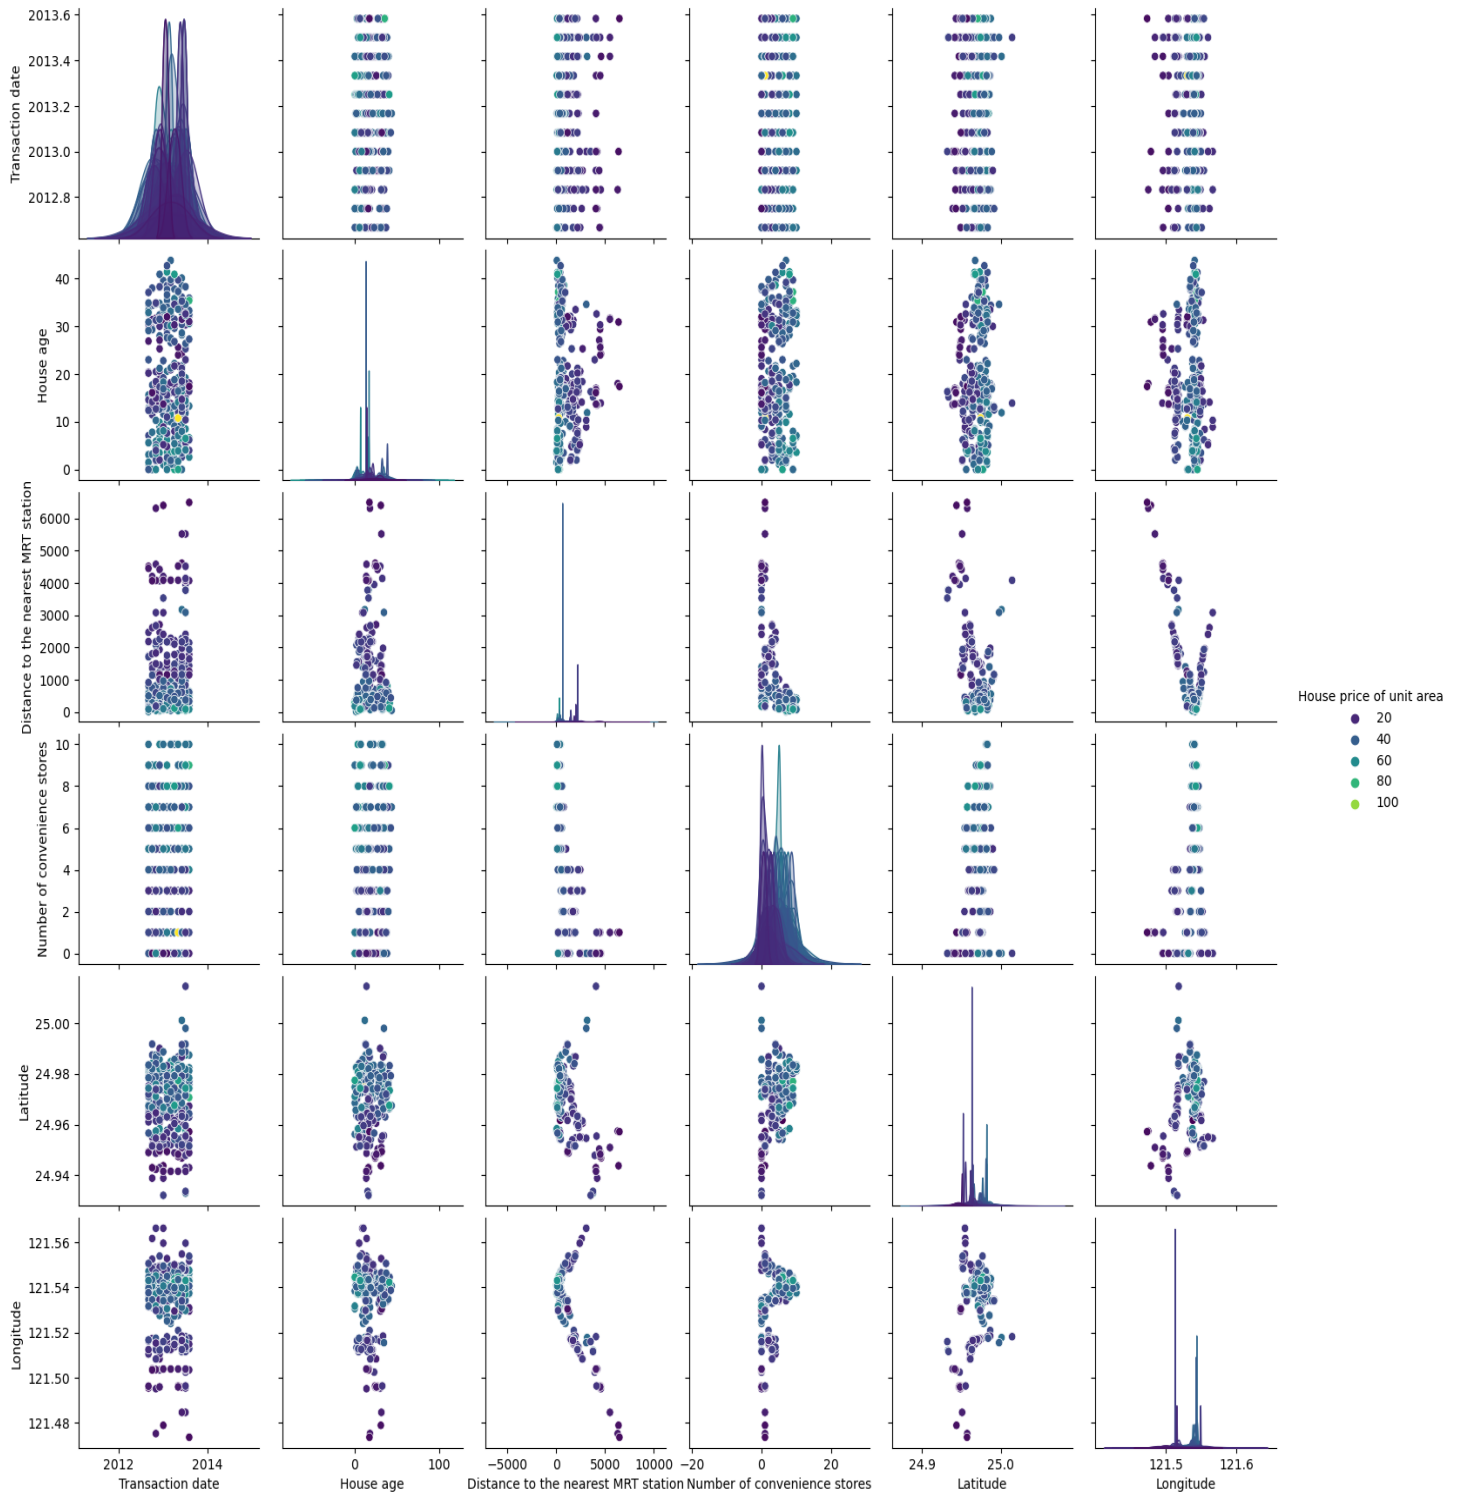

Figure 6: Pair plots for real estate dataset

### 3.2 Heat map

To identify the correlation between variables of datasets, heatmaps were used.

Figure 7: Heatmap for insurance dataset

Figure 8: Heatmap for real estate dataset

## **4 Data preprocessing**

### **4.1 Converting the Categorical Data into numerical**

Only Insurance dataset contained the categories data namely 'sex, smoker, and region' columns. One Hot Encoding technique was implemented to achieve this target. Following procedure was adopted.

- Dummy variables were created corresponding to the categorical attributes using 'get\_dummies()' command
- These dummy variables were concatenated with the actual data set.
- The actual categorial attributes columns were dropped off from the data set to get pure numerical dataset

The implementation of the above procedure can be seen in the code.

### **4.2 Dividing the Actual data into 'feature' and 'label' datasets**

The actual datasets were divided into two new date sets. All the independent variables were assigned a dataset 'feature' and all the single dependent variable was assigned the dataset 'label'.

### **4.3 Splitting the data into test and train data set**

For model building and validation, the data were split in two parts: 70 percent data for model training and 30 percent data for model testing. For this purpose, 'train\_test\_split()' function was used from 'sklearn' library.

## 5 Selection and training the model

Initially sklearn's LinearRegression() module was implemented with StandardScaler normalization technique. The mean absolute error and score on training and test data are give in the following table.

**Table 1: Results of LinearRegression model**

<b>Insurance Data</b>		
	<b>Training Data</b>	<b>Test Data</b>
<b>MAE</b>	4194.3	4194.3
<b>Score</b>	0.744	0.767
<b>Real estate Data</b>		
	<b>Training Data</b>	<b>Test Data</b>
<b>MAE</b>	6.09	6.96
<b>Score</b>	0.576	0.579

### 5.1 Feature Scaling

Next model was tested for following 3 scaling techniques:

- Standard Scalar
- Z score
- Log transform

This time sklearn's SGDRegressor model was implemented. Following table contains the errors related to above mentioned normalization techniques.

**Table 2: Result of SGDRegressor model with different data transforms**

<b>Insurance Data</b>						
	<b>Standard Scaler</b>		<b>Z score</b>		<b>Log transform</b>	
	<b>Training Data</b>	<b>Test Data</b>	<b>Training Data</b>	<b>Test Data</b>	<b>Training Data</b>	<b>Test Data</b>
<b>MAE</b>	4172	4229	4172	4179	4689	4574
<b>Real estate Data</b>						
<b>MAE</b>	6.26	5.87	6.43	6.26	5.846	5.44

It is obvious from the above table that standard scaler transform produces least errors for insurance data and log transform produces least errors for real estate data.

## 5.2 Hyper parameter tuning

Sklearn contains a bunch of linear regression modules with plenty of hyper parameters. Therefore it becomes nearly impossible to check each module with various hyper parameters to find an optimum model for the given dataset. To ease the difficulty of selecting suitable hyperparameters, sklearn provides a function "GridSearchCV". GridSearchCV can take a number of models with various values for hyperparameters. It then processes the given data with different combinations of hyperparameters. This enables it to identify the most appropriate model and the optimal hyperparameter values that yield the best performance.

Following is detail of inputs that were given to GridSearchCV:

### **Estimator:**

LinearRegression(), SGDRegressor()

LinearRegression() was set for default values of hyperparameters. Only SGDRegressor() was evaluated for different hyper parameter values.

**Table 3: Range of Hyperparameter values for SGDRegressor**

Hyper parameter	Value range
Feature Scaling	StandardScaler(), log_transform, zscore_transform
Regularization techniques	l1(lasso regression), l2(ridge regression), elasticnet
Regularization parameter	0.0001, 0.001, 0.01, 1
Warm start	True, False
Learning Rate	0.01, 0.001, 0.02
Tolerance	0.001

After processing the above input values, GridSearchCV came up with following suitable values for hyper parameters.

**For Insurance data:**

**Table 4: Hyper parameter values for insurance data**

Hyper parameter	Value
Feature scaling	StandardScaler()
Estimator	SGDRegressor
Regularization techniques	l1(lasso regression)
Regularization parameter	1
Learning rate	0.001
Warm start	True
Tolerance	1e-3

**For real estate data:**

**Table 5: Hyper parameter values for real estate data**

<b>Hyper parameter</b>	<b>Value</b>
Feature scaling	StandardScaler()
Estimator	SGDRegressor
Regularization techniques	l2(Ridge regression)
Regularization parameter	0.01
Learning rate	0.02
Warm start	True
Tolerance	1e-3

The detailed implementation of GridsearchCV can be found in the code.

## 6 Evaluation of hyperparameters obtained through GridsearchCv method

For both the datasets, SGDRegressor model was found to be the most appropriate. The accuracy of the model was tested based on the hyperparameter values obtained, and various evaluation metrics were used to access its performance.

### 6.1 Gradient Convergence:

For both the data sets, gradient converged before reaching 50 iterations.

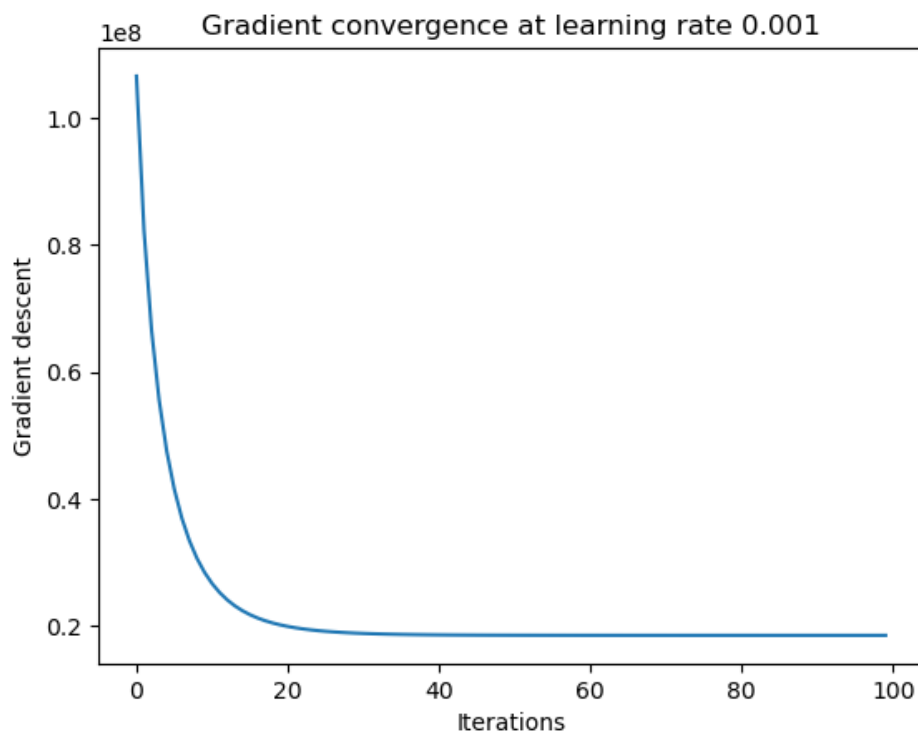

Figure 9: Gradient convergence for insurance data

**Figure 10: Gradient convergence for real estate data**

## 6.2 Training Loss and accuracy

The training loss was calculated in terms of mean absolute error between the predicted values for labels and actual label values of train portion of datasets.

**Figure 11: Training loss for insurance data**

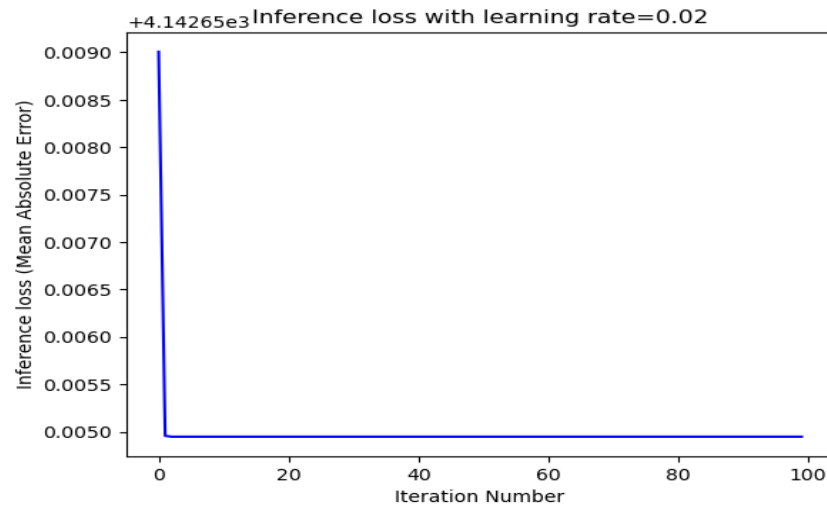

**Figure 12: Training loss for real estate data**

In case of train data, mean absolute error was 4195 for insurance data and 6.28 for real estate data. The accuracy of model for insurance data remained 0.744 and that for real estate data was 0.57.

### 6.3 Inference loss and accuracy

The inference loss was calculated in terms of mean absolute error between the predicted values for labels and actual label values test portion of datasets.

**Figure 13: Inference loss for insurance data**

**Figure 12: Inference loss for real estate data**

For test data, mean absolute error was 4237 for insurance data and 5.6 for real estate data. The accuracy of model for insurance data remained 0.766 and that for real estate data was 0.579.
